We present results from a search for gravitational-wave bursts in the data collected by the LIGO and Virgo detectors between July 7, 2009 and October 20, 2010: data are analyzed when at least two of the three LIGO-Virgo detectors are in coincident operation, with a total observation time of
207 days. The analysis searches for transients of duration \(\lesssim 1\) s over the frequency band 64–5000 Hz, without other assumptions on the signal waveform, polarization, direction or occurrence time. All identified events are consistent with the expected accidental background. We set frequentist upper limits on the rate of gravitational-wave bursts by combining this search with the previous LIGO-Virgo search on the data collected between November 2005 and October 2007. The upper limit on the rate of strong gravitational-wave bursts at the Earth is 1.3 events per year at 90% confidence. We also present upper limits on source rate density per year and Mpc\(^3\) for sample populations of standard-candle sources. As in the previous joint run, typical sensitivities of the search in terms of the root-sum-squared strain amplitude for these waveforms lie in the range \(\sim 5 \times 10^{-22}\) Hz\(^{-1/2}\) to \(\sim 1 \times 10^{-20}\) Hz\(^{-1/2}\). The combination of the two joint runs entails the most sensitive all-sky search for generic gravitational-wave bursts and synthesizes the results achieved by the initial generation of interferometric detectors.

PACS numbers: 04.80.Nn, 07.05.Kf, 95.30.Sf, 95.85.Sz

I. INTRODUCTION

Astrophysical sources of transient gravitational waves (duration of \(\lesssim 1\) s) \(^1\) include merging compact binary systems consisting of black holes and/or neutron stars \(^2\) \(^3\), core-collapse supernovae \(^4\), neutron star collapse to black holes \(^5\), star-quakes associated with magnetar flares \(^6\) or pulsar glitches \(^7\), cosmic string cusps \(^8\), and other violent events in the Universe. Since many classes of gravitational-wave (GW) bursts cannot be modeled well – if at all – a search for those sources must be sensitive to the widest possible variety of waveforms.

This paper reports on a search for GW bursts occurring during the second joint observation run of the LIGO \(^9\) and Virgo \(^10\) detectors, which took place in 2009–2010. This search makes no prior assumptions on source sky location, signal arrival time, or the waveform itself. Event rate upper limits from long-term searches of this category have been derived with networks of resonant bar detectors with spectral sensitivity limited to around 900 Hz in 1997–2000 \(^1\)\(^1\)\(^2\)\(^3\) and in 2005–2007 \(^1\)\(^3\)\(^1\)\(^4\). Networks of interferometric detectors set more stringent upper limits for GW bursts on a wider bandwidth using the LIGO detectors in 2005–2006 \(^1\)\(^5\)\(^1\)\(^7\) and during the first joint observation of LIGO and Virgo detectors in 2007 \(^1\)\(^8\).

This second joint LIGO-Virgo search for GW bursts analyzed the frequency band spanning 64–5000 Hz. We achieved a frequency-dependent sensitivity comparable to or better than that of the first joint run, and accumulated \(\sim 207\) days of observation time interlaced with periods of installing or commissioning major hardware upgrades. Moreover, for the first time a low-latency analysis was run with the goal of providing triggers for electromagnetic follow-ups of candidates by robotic optical telescopes \(^1\)\(^9\), radio telescopes, and the Swift satellite \(^2\)\(^0\)\(^1\)\(^1\)\(^2\). In this paper we focus on the final results of the GW stand-alone search, which found no evidence for GW bursts.

This paper is organized as follows. In Section \(\text{II}\) we describe the second joint scientific run: we report on the LIGO and Virgo instrumental upgrades with respect to the first run and on data quality studies. In Section \(\text{II}\)\(^1\) we give a brief overview of the search: the search algo-

\(^1\) The 2 km detector at the Hanford site (H2) was decommissioned before the second joint LIGO-Virgo run. During previous runs, the latter detector was mainly used to enforce additional event selection criteria by taking advantage of the special relationship for GW signals from the co-located interferometers H1 and H2.
FIG. 1: Noise spectra for the three LSC-Virgo detectors achieved during S6-VSR2/3.

expected to start observations in 2015. The upgrades of the LIGO detectors for S6 include a higher power 35 W laser, the implementation of a DC readout system, a new output mode cleaner, and an advanced LIGO seismic isolation table [27]. The upgrades of the Virgo detectors were achieved in two steps. For VSR2, Virgo operated with a more powerful laser and a thermal compensation system. Virgo then went offline to install new test masses consisting of mirrors hung from fused silica fibers [28]. Virgo resumed observations in August 2010 with VSR3. Best sensitivities, in terms of noise spectral densities, of the LIGO and Virgo detectors achieved during their second joint run (henceforth defined as S6-VSR2/3), as a function of signal frequency, are shown in Figure 1.

B. Data Quality

To mitigate the consequences of new hardware installations and detector commissioning during this run, significant effort has been made to identify and characterize instrumental or data acquisition artifacts, periods of degraded sensitivity, or an excessive rate of transient noise due to environmental conditions [29]. During such times, the data were tagged with Data Quality Flags (DQFs). Following the same approach used in previous searches [16–18], these DQFs are divided into three categories depending on their impact on the search and on the understanding of the behavior of the detector. A further description of DQF categories is presented in Appendix A.

After DQFs have been applied, the total analyzable time for the S6-VSR2/3 run is 242.8 days for H1, 220.2 days for L1, and 187.8 days for V1.

III. SEARCH OVERVIEW

In this analysis, we considered all four available detector network configurations: the three detector network, H1L1V1, and the three combinations of detector pairs, H1L1, H1V1, and L1V1. We decided a priori to search for GW bursts in the entire available time of three-fold observation and in the remaining exclusive times of the two-fold networks. Table I reports the total (non-overlapping) coincident observation time for each configuration of detectors searched for GW signals. Information about distinct sub-periods of the run may be found in Appendix C.

Due to the commissioning breaks and installation activities described in Section II, the total observation time is dominated by 2-fold configurations.

TABLE I: Mutually exclusive observation time for each detector configuration after the application of category 2 DQFs (see Appendix A for the definition of data quality flags and their categories).

The useful frequency band is limited to 64–5000 Hz by the sensitivity of the detectors and by the valid range of data calibration. For computational reasons, the event search was performed separately in two suitable bands, 64–2048 Hz and 1600–5000 Hz, overlapping to preserve sensitivity to events with spectral power at intermediate frequencies. The analysis of the events (including the tuning of the search) was performed independently on each configuration of detectors and on three sub-bands, namely 64–200 Hz, 200–1600 Hz and 1600–5000 Hz, by classifying the found events according to their reconstructed central frequency. The motivation for this band splitting is to tune the search within event sets of homogeneous glitch behaviour.

A. Search Algorithm

This search is based on the coherent WaveBurst (cWB) algorithm [30], which has been used since LIGO’s fourth science run in various searches for transient GWs [16–18 31].

The cWB analysis is performed in several steps. First, detector data is decomposed into a time-frequency representation and then whitened and conditioned to remove narrow-band noise features. Events are identified by clustering time-frequency pixels with significant energy which is coherent among detectors and characterized using test statistics derived from the likelihood (which is also a measure of the signal energy detected in the network and is calculated as described in [16]). The primary statistics are the network correlation coefficient $c$, which is a measure of the degree of correlation between the detectors, and the coherent network amplitude $\eta$, which is
proportional to the signal-to-noise ratio and is used to rank events within a homogeneous sub-period.

Both of these statistics are described in detail in [16]. The application of the event selection criteria is thoroughly described in [18, 32].

Any gravitational-wave candidate event detected by eWB is subject to additional data-quality vetoes based on statistical correlations between the GW data channel and environmental and instrumental auxiliary channels; a significant correlation indicates the event may have been produced by local noise. Further details can be found in Appendix [B].

B. Background Estimation and Search Tuning

A sample of “off-source” (background) events is required to determine the selection thresholds to reject noise-induced events contaminating the “on-source” (foreground) measurement. We estimate the distribution of background events by performing the analysis on time-shifted data, typically in ~ 1 s steps. The shifts minimize the chance of drawing an actual GW into the background sample. To accumulate a sufficient sampling, this shifting procedure is performed hundreds or thousands of times without repeating the same relative time shifts among detectors. Background events corresponding to times which are flagged by data quality studies are discarded, just as an event candidate from the foreground would be.

Due to the different characteristics of the background noise for the various sub-periods between commissioning breaks and for the different frequency bands and networks, the thresholds on $c c$ and $\eta$ are tuned separately for each homogeneous sub-period. Moreover, we consider the action of conditional DQFs (Category 3 DQFs, see Appendix [A]) on the event significance, by introducing a new ranking scheme which assigns lower significance to events flagged by such DQFs. More details on this procedure are reported in Appendix [D].

The thresholds reported in Table VII in Appendix [D] are selected to require a false alarm rate (FAR) $\lesssim 1/(8 \text{ yr})$ per frequency band. This choice for the FAR threshold corresponds to an overall false alarm probability (FAP) of ~ 15% when considering the union of all searches performed (network configurations, sub-periods, and frequency bands). Single ”on-source” events at higher FAR are discarded as non-significant. Any ”on-source” event passing the FAR threshold would instead be selected for further follow-ups investigations. Namely, we would check for any additional evidence about its origin and we would refine the measurement of its statistical significance (i.e. by performing additional independent time-shifted analyses to increase the statistics of the background estimates). This FAR threshold sets the overall sensitivity of the search.

C. Simulated Signals and Detection Efficiencies

In order to test the sensitivity of our search to gravitational-wave bursts, we add (“inject”) various ad-hoc software signals, both polarized and un-polarized, to the detector data and measure the detection efficiencies of the search. The injected waveforms can be parametrized as:

$$
\begin{bmatrix}
    h_+(t) \\
    h_\times(t)
\end{bmatrix} = A \times \left[ \frac{1+\alpha^2}{2} \right] \times \begin{bmatrix}
    H_+(t) \\
    H_\times(t)
\end{bmatrix},
$$

where $A$ is the amplitude, $\alpha$ the ellipticity $^2$ and $H_+/-\times$ are the waveforms for the two independent polarizations.

In this search, we investigated elliptically polarized signals (i.e. $\alpha$ uniformly chosen in $[0, 1]$), as well as sets of only linearly or circularly polarized waves ($\alpha$ fixed to 0 or 1, respectively). A variety of GW signal morphologies spanning a wide range of signal durations, frequencies and amplitudes were tested. See Figure [2] for a sample of representative waveforms from various families and Tables [II, III, IV] for the chosen waveform parameters.

The injected waveform families include:

- **Sine-Gaussian:**
  $$H_+(t) = \exp(-t^2/\tau^2) \sin(2\pi f_0 t) \quad (3.2)$$
  $$H_\times(t) = \exp(-t^2/\tau^2) \cos(2\pi f_0 t) \quad (3.3)$$
  where $\tau = Q/(\sqrt{2\pi f_0})$. We consider waveforms of this type with central frequencies $f_0$ chosen between 70 to 5000 Hz and quality factors $Q = 3, 9, 100$. Sine-Gaussian waveforms with a few cycles are qualitatively similar to signals produced by the mergers of two black holes [2].

- **Gaussian:**
  $$H_+(t) = \exp(-t^2/\tau^2) \quad (3.4)$$
  $$H_\times(t) = 0 \quad (3.5)$$
  where the duration parameter $\tau$ is chosen to be one of 0.1, 1.0, 2.5, or 4.0 ms.

- **Ring-down waveforms:**
  $$H_+(t) = \exp(-t/\tau) \sin(2\pi f_0 t) \quad (3.6)$$
  $$H_\times(t) = \exp(-t/\tau) \cos(2\pi f_0 t) \quad (3.7)$$
  We use several central frequencies from 1590 Hz to 3067 Hz, and decay times $\tau = 0.2$ s or $Q = 9$. Ring-downs can occur in the end stages of black hole binary mergers. Longer duration ring-downs are also similar to signals predicted from the excitation of fundamental modes in neutron stars [33].

---

$^2$ For binary sources, the ellipticity is the cosine of the source inclination angle, i.e. the angle between the source rotational axis and the line of sight to Earth.
FIG. 2: Representative waveforms injected into data for simulation studies. The top row is the time domain and the bottom row is a time-frequency domain representation of the waveform. From left to right: a 361 Hz $Q = 9$ sine-Gaussian, a $\tau = 4.0$ ms Gaussian waveform, a white noise burst with a bandwidth of 1000–2000 Hz and characteristic duration of $\tau = 20$ ms and, finally, a ringdown waveform with a frequency of 2000 Hz and $\tau = 1$ ms.

- **Band-limited white noise signals:**
  The polarization components are bursts of uncorrelated band-limited white noise, time shaped with a Gaussian profile; $H_+$ and $H_\times$ have — on average — equal RMS amplitudes and symmetric shape about the central frequency (see Figure 2).

- **Neutron star collapse waveforms:**
  For a comparison with previous searches [17, 18], we considered numerical simulations by Baiotti et al. [5], who modeled neutron star gravitational collapse to a black hole and the subsequent ring-down. As in previous searches, we chose the models D1 (a nearly spherical 1.67 M$_\odot$ neutron star) and D4 (a 1.86 M$_\odot$ neutron star that is maximally deformed at the time of its collapse into a black hole) to represent the extremes of the parameter space in mass and spin considered in the aforementioned work. Both waveforms are linearly polarized ($H_\times = 0$) and their emission is peaked at a few kHz.

The simulated signals were injected with many amplitude scale factors to trace out the detection efficiency as a function of signal strength. The amplitude of the signal is expressed in terms of the root-sum-square strain amplitude ($h_{rss}$) arriving at the Earth, defined as:

$$h_{rss} = \sqrt{\int |h_+(t)|^2 + |h_\times(t)|^2}$$  \hspace{1cm} (3.8)

The signal amplitude at a detector is modulated by the detector antenna pattern functions, expressed as follows:

$$h_{det}(t) = F_+(\Theta, \Phi, \psi)h_+(t) + F_\times(\Theta, \Phi, \psi)h_\times(t)$$  \hspace{1cm} (3.9)

where $F_+$ and $F_\times$ are the antenna pattern functions, which depend on the orientation of the wavefront relative to the detector, denoted here in terms of the sky position ($\Theta, \Phi$), and on the polarization angle $\psi$. The sky positions of simulated signals are distributed isotropically and polarization angles are chosen to be uniformly distributed.

The detection efficiency is defined as the fraction of signals successfully recovered using the same selection thresholds and DQFs as in the actual search. The detection efficiency of the search depends on the network configuration and the selection cuts used in the analysis. Detection efficiencies for the H1L1V1 network for selected waveforms as a function of signal amplitude $h_{rss}$ and as a function of distance (for the D1 and D4 waveforms from Baiotti et al. [5]) are reported in Figures 3 and 4, respectively. As in the previous joint run, typical sensitivities for this network in terms of $h_{rss}$ for the selected waveforms lie in the range $\sim 5 \times 10^{-22}$ Hz$^{-1/2}$ to $\sim 1 \times 10^{-20}$ Hz$^{-1/2}$; typical distances at 50% detection efficiency for neutron star collapse waveforms lie in the range $\sim 50$ pc to $\sim 200$ pc.

Two convenient characterizations of the sensitivity, the $h_{rss}$ at 50% and 90% detection efficiency ($h_{50\% rss}$ and $h_{90\% rss}$ respectively) are obtained from fitting the efficiency curves and are reported in Tables II, III, and IV for the various families. Notice that the 3-fold network, H1L1V1, has a better sensitivity than the weighted average over all networks: 2-fold networks have $\sim 3/4$ of the analyzed live time, but feature a lower sensitivity.

D. Systematic Uncertainties

The most relevant systematic uncertainty in the astrophysical interpretation of our results is due to the calibration error on the strain data produced by each detector [34, 35]. The effect of calibration systematics on network detection efficiency has been estimated by dedicated simulations of GW signals in which the signal am-
FIG. 3: Detection efficiency for selected waveforms as a function of signal amplitude $h_{rss}$ for the H1L1V1 network. Top: Comparison of detection efficiency for linear (L) and elliptical (E) sine-Gaussians with central frequencies of 235 and 1304 Hz. Middle: Comparison of detection efficiency for linear (L) and circular (C) ring-down signals with frequencies of 2090 and 2590 Hz. Bottom: Detection efficiency for white noise bursts with frequency spanning between 100 and 4500 Hz.

FIG. 4: Efficiency for the H1L1V1 network as a function of distance for the D1 and D4 waveforms predicted by polytropic general-relativistic models of neutron star collapse.

tainties over the observation time. The main effect can be parametrized as an overall shift of the detection efficiency curves along the signal strength axis. The largest effect over the injected signal waveforms was a 8% increase of the $h_{rss}$ amplitude at fixed detection efficiency.

To produce the astrophysical limits shown in Section IV, we use the reduced detection efficiency curves obtained by shifting the original fits from Subsection III C and the results in Tables II, III, and IV to 8% larger $h_{rss}$ values.

IV. SEARCH RESULTS

The on-source data have been analyzed following the procedures tuned through the investigation of the off-source background sample, as described in Appendix D. No on-source event has been found above the threshold false alarm rate of once in 8 years per frequency band, and the distribution of on-source events is in agreement with the measured background. Table V lists the five most significant on-source events, as ranked by their Inverse False Alarm Rate (IFAR = 1/FAR), and taking into account the trial factor due to the three independent searches performed on the disjoint frequency bands.

In addition to the events reported in Table V, this search also detected an on-source event showing a chirping waveform compatible with a compact binary coalescence at a signal-to-noise ratio $\sim 17$ in the H1L1V1 network. This event was first identified by a low-latency

Note that, due to an incomplete knowledge of the actuation resonances in $[3000,4000]$ Hz band of the Hanford detector, very conservative assumptions have been made on calibration uncertainties; the networks including H1 in that frequency band feature a large efficiency loss due to calibration systematics of 24%.
TABLE II: Values of $h_{50\%}^{\text{rss}}$ and $h_{90\%}^{\text{rss}}$ (for 50% and 90% detection efficiency at the chosen thresholds of 1/(8 yr) per frequency band), in units of $10^{-22} \text{ Hz}^{-1/2}$, for linear and elliptical sine-Gaussian waveforms with the central frequency $f_0$ and quality factor $Q$. The center two columns are the $h_{50\%}^{\text{rss}}$ for linear and elliptical waveforms during the total S6 period measured for the H1L1V1 network. The rightmost columns report the values of $h_{50\%}^{\text{rss}}$ and $h_{90\%}^{\text{rss}}$ over the whole S6-VSR2/3 for the combined results (i.e. averaged over time) from all the networks.

burst search within minutes of its occurrence on September 16, 2010 and was thoroughly investigated in follow-up studies. Its Inverse False Alarm Rate was estimated at 1.1 yr from comparison with the burst reference background over all trials. After the completion of the analysis, this event was revealed to be a blind hardware injection [36] intended as an end-to-end test of the search for transient signals 4. As such, the event was removed from the final results.

4 Signal injections were performed via direct excitation of the interferometer mirror test masses. Some of these hardware injections were intended to mimic a coherent GW excitation across the network and to provide an end-to-end verification of the detector instrumentation, the data acquisition system and the data analysis software. In addition to those, a blind injection challenge was realized consisting of injecting a few simulated signals at times not announced to the collaborations. This was done for the purpose of testing the data analysis pipelines and event validation protocols.

### A. Upper Limits

The new null result can be combined with the previous ones from the latest scientific runs by LIGO and Virgo [16][18] to complete the results achieved by initial generation interferometric detectors.

Assuming a Poisson distribution of astrophysical sources and in the special case of no surviving candidate events, the 90% confidence upper limit is computed as in [37]:

\[
R_{90\%} = \frac{2.3}{\sum k \epsilon_k T_k},
\]

where \(2.3 = -\log(1 - 0.9)\), \(\epsilon_k\) and \(T_k\) are respectively the detection efficiency (calculated with selection thresholds as in Section 11B) and the observation time of the network configuration \(k\), including all available LIGO and LIGO–Virgo observations since November 2005 [16][18].

Figure 5 shows the upper limits on the rate of gravitational-wave bursts at the Earth as a function of signal strength \(h_{rss}\) for selected sine-Gaussian waveforms. The second joint LIGO–Virgo run increases the previous total observation time by roughly 50%, totaling 1.74 yr. Therefore, the resulting 90% upper limit on the rate for strong signals (asymptotic behaviour for \(\epsilon_k \to 100\%\)) decreases from 2.0 to 1.3 yr\(^{-1}\) for the 64 – 1600 Hz band (from 2.2 to 1.4 yr\(^{-1}\) for the band above 1.6 kHz).

The results can also be interpreted as limits on the rate density of GW bursts (number per year and per Mpc\(^3\)) assuming a standard-candle source, isotropically distributed, as previously reported in [18]. Denoting by \(h_0^2\) the average value of the GW squared amplitude \(h_{rss}^2\) at a fiducial distance \(r_0\) from the source, the energy converted to GWs is

\[
E_{GW} = \frac{\pi^2 c^3}{G} r_0^2 f_0^2 h_0^2.
\]

where \(f_0\) is the central frequency of GW emission.

#### TABLE V: The five most significant events present in the on-source data. IFAR is the Inverse False Alarm Rate [yr] of the event in the entire search, SNR is the signal-to-noise ratio in the whole network, and FAP is the false alarm probability (probability of getting at least as many accidental events as those observed with IFAR ≥ the value reported in the first column).

Considering a population of standard-candle sources randomly oriented with respect to the Earth and at a distance \(r_0\), we can interpret the \(h_0^2\) as the average GW squared amplitude impinging on the Earth (e.g. averaged over source parameters such as inclination angle). Equation 4.2 can then be used to estimate \(h_0(E_{GW}, f_0, r_0)\) and in particular sets the inverse proportionality between the average \(h_{rss}\) at Earth and source distance \(r\): \(hr = h_0r_0\).

Assuming a uniform distribution in the sky and in time of these standard-candle sources, the expected rate of detections is

\[
N_{\text{det}} = 4\pi\mathcal{R}T \int_0^{\infty} dr r^2 \epsilon(r)
\]

\[
= 4\pi\mathcal{R}(h_0r_0)^3 \int_0^{\infty} dh h^{-4} \epsilon(h).
\]

where \(\mathcal{R}\) is the rate density of the standard-candle sources, \(T\) the overall observation time, and \(\epsilon(h)\) the detection efficiency as measured by our simulations.

Hence, the 90% confidence upper limit on rate density \(\mathcal{R}\) of such standard-candle sources is

\[
\mathcal{R}_{90\%} = \frac{2.3}{4\pi T(h_0r_0)^3} \int_0^{\infty} dh h^{-4} \epsilon(h).
\]

The resulting \(\mathcal{R}_{90\%}\) is dominated by the part of the detection efficiency curve at small GW amplitude \(h\). Due to the relative orientations of the LIGO-Virgo detectors, detection efficiency curves for linearly polarized sine-Gaussian waveforms are approximately the same of those for elliptically polarized ones; the numerical values of \(\mathcal{R}_{90\%}\) are close within a few percent for both source models.

Figure 6 shows the rate density upper limits of sources as a function of frequency. This result can be interpreted in the following way: given a
standard-candle source with a characteristic frequency $f$ and energy $E_{GW}$, the corresponding rate limit is $R_{90\%}(f)(M_\odot c^2/E_{GW})^{3/2} \text{ yr}^{-1}\text{Mpc}^{-3}$.

The typical GW energy in units of solar masses for LIGO-Virgo observation is shown in Figure 7 computed with Equation 4.2 using the measured $h_{rss}$ at 50% detection efficiency for the tested waveforms assuming a standard candle source emitting at a distance of 10 kpc. The mass scales with the square of the fiducial distance and the results are robust over the very wide class of waveforms tested. As expected, the GW energy is strongly dependent on the spectral sensitivity of the network, with a negligible dependence on the specific waveform characteristics.

V. SUMMARY AND DISCUSSION

This paper reports the results achieved by the LIGO and Virgo detectors in the search for GW transients of duration $\lesssim 1$ s, without assumptions on the signal waveform, polarization, direction or arrival time.

Three detectors were operating at the Hanford, Livingston and Pisa sites during the second joint observation of LIGO and Virgo in 2009-2010. The detectors implemented hardware upgrades in order to prototype new subsystems planned for the upcoming advanced detectors. The resulting sensitivities to GWs were comparable to those achieved during the first LIGO-Virgo run. The main contribution of the second run is a 50% increase in accumulated observation time.

No event candidates were found in this search. We set better upper limits on the rate of gravitational-wave bursts at Earth and on the rate density of burst sources per unit time and volume. These limits combine all available information from the LIGO–Virgo joint runs and set the state-of-the-art on all-sky searches for transient gravitational waves of short duration.

The reported $h_{rss}$ amplitude of the GW at Earth can be converted into the energy emitted by a source at some fiducial distance assuming a simple model as in Equation 4.2. For example, the energy emitted in gravitational waves in units of solar masses at a distance of 10 kpc and considering measured $h_{rss}$ at 50% detection efficiency (Table II) is $\simeq 2.2 \cdot 10^{-8}M_\odot$ at 150 Hz (5.6 $\cdot 10^{-2}M_\odot$ at 16 Mpc). These GW energies, though obviously depending on the signal frequency, are approximately constant over different polarization models of the GW emission, including linearly polarized sources, circularly polarized sources and unpolarized emission with random polarization amplitudes (see Tables II, III, and IV).

The long baseline interferometric detectors LIGO and Virgo are currently being upgraded to their advanced configurations, and the next joint observation is planned for 2015. Another advanced detector, LCGT [38, 39], is being built in Japan, and there are proposals to realize an additional advanced LIGO detector outside the USA. These advanced detectors should achieve strain sensitivities a factor of ten better than the first-generation detectors. For example, at design sensitivity these detectors should detect a typical core-collapse supernova anywhere in the galaxy [40] and will be able to put constraints on extreme scenarios for core collapse supernovae within the Local Group [41]. Other possible short duration sources, such as the merger of very high mass stellar black hole binaries, could be visible at distances exceeding 1 Gpc. During advanced detector observations, gravitational-wave detections are predicted to occur on
a regular basis [12], thus greatly expanding the field of gravitational-wave astrophysics.

Acknowledgments

The authors gratefully acknowledge the support of the United States National Science Foundation for the construction and operation of the LIGO Laboratory, the Science and Technology Facilities Council of the United Kingdom, the Max-Planck-Society and the State of Niedersachsen/Germany for support of the construction and operation of the GEO 600 detector, and the Italian Istituto Nazionale di Fisica Nucleare and the French Centre National de la Recherche Scientifique for the construction and operation of the Virgo detector. Sloan Foundation. This document has been assigned LIGO Laboratory document number LIGO-P1100118-v16.

APPENDIX A: DATA QUALITY FLAGS

Data Quality Flags (DQFs) are intended to indicate periods of data taking which suffer from environmental and instrumental effects inducing noise into the data [29]. We followed the DQF strategy used in previous searches [16] [18], organizing DQFs into 3 categories. The different categories reflect the level of understanding of the detectors’ performances as well as of the relation between disturbances in the data set and environmental or instrumental causes.

Category 1 DQFs mark segments of time (typically more than tens of seconds) when disturbances make analysis unfeasible. Data segments remaining after their application are used in the analysis.

Category 2 DQFs are connected to well-understood short duration (typically a few seconds) periods of noise transients. Data segments flagged by this category can be used for data conditioning and noise property estimation, but events emerging from these periods are discarded as very likely originating from the detector environment.

Finally, Category 3 DQFs denote periods that are only weakly correlated to environmental and instrumental monitors. Such cuts are not reliable enough to be used as unconditional cuts. When applied to events generated by the search algorithm, they would reject a significant fraction (in extreme cases up to 15-20%) of data. Their use is limited to significance calculations using the MIFAR statistic (see Appendix D).

APPENDIX B: EVENT-BY-EVENT VETOES

Often, GW candidate events identified in the on-source time can be linked to disturbances propagating through the detector from the environment or within the detector itself. Our procedure for identifying such event-by-event vetoes in S6 and VSR2/3 follows that used in S5 and VSR1 [16] [18]. The GW channel and a large number of auxiliary channels are processed with the Kleine-Welle [15] algorithm, which looks for excess power transients. A hierarchical method [44] is used to rank the statistical relationship between the transients found in the auxiliary channels and those found in the detector output. Based on these rankings, vetoes are defined for suspected noise events. Another veto used was based on significant statistical association of events observed in the GW channel and the auxiliary channels [15].

An additional set of Category 3 vetoes [45] are applied to events emerging from networks including Virgo; vetoes from this set are based on detector read-out channels which are known to be insensitive to gravitational waves.

Procedurally, the event-by-event vetoes are applied with the same conditions as their corresponding Category of data quality flags described in Appendix A.

APPENDIX C: DETECTOR NETWORKS AND LIVE TIMES

The total observation time for the analysis has been divided into four sub-periods (labeled A, B, C and D), separated by planned commissioning and upgrade breaks which changed the performance of the detectors. Table VI shows the observation time of each network configuration after the application of Category 1 and 2 DQFs. These times are not overlapping. During the period from January to June 2010 (sub-period C), Virgo did not participate in the run because of hardware upgrades.

APPENDIX D: MODIFIED INVERSE FALSE ALARM RATE (MIFAR)

We introduce the Modified Inverse False Alarm Rate (MIFAR) to account for the effect of Category 3 DQFs on the background.

Category 3 DQFs indicate a weak statistical correlation of the GW data with environmental and instrumen-
tal noise sources, and thus were used only as a caution-
ary tag when examining an event in candidate follow-ups.
Moreover, the effectiveness of these flags is not constant
between different sub-periods, network configurations or
frequency bands. The use of Category 3 data quality as
a tag allows us to produce two sets of events: the “raw”
set (polluted to some extent by noise glitches) and the
subset of those events that are not tagged, the “clean”
set (with reduced observation time).

In order to account for the difference in background
distributions when assessing the significance of candidate
GW events from the raw and clean sets, we use the fol-
lowing procedure:

1. Within each homogeneous analysis (same detec-
tor’s configuration, same tuning of analysis, same
frequency band), we rank events from the two sets
separately by their coherent network amplitude $\eta$; 
$i.e.$, if the event candidate is flagged by Category
3 data quality, it is ranked against the raw set of
events, otherwise it is ranked against the clean set.

2. Each event is then assigned a MIFAR as the inverse
of the rate of higher-ranked background events in
that set, $i.e.$ the MIFAR is the IFAR of the event
considering only that set.

3. We merge the events from the raw and clean sets
into a single list, sorted by the MIFAR. For events
with equal MIFAR the one with larger $\eta$ is ranked
higher. This ranking is performed separately for
each homogeneous analysis.

4. According to this merged ranking, we measure the
IFAR of the events as the rate of the corresponding
background event with equal MIFAR. This mea-
sured IFAR is used as our “universal” ranking for
all events in all analyses.

5. The final IFAR of any event over the entire search
is just 1/3 of the value estimated in the previous
step because of the trials factor: three independent
analyses have been performed for the three disjoint
frequency bands. No contribution to the trials fac-
tor comes from the analyses of different detectors’
configuration since these were performed on non-
overlapped observation times.

In each homogeneous analysis, setting a threshold on
IFAR corresponds to two thresholds on $\eta$, one for the
raw set and one for the clean data set. Table VII reports
the selected thresholds. These thresholds were tuned using
the background and injection events, without considering
the on-source events to avoid bias in candidate selection.

TABLE VI: Observation time for each detector configuration after application of Category 1 and 2 DQFs for the four sub-
periods A, B, C, and D. For period A, the observation time of
the H1L1 network after subtracting the H1L1V1 observation
time is negligible ($\sim$ 1 day). During period C, Virgo did not
participate in the run.

TABLE VII: Thresholds per network, sub-period and frequency band for the homogeneous analyses performed. The threshold $\eta_1$ is applied to the events in the raw set (those in coincidence with a Category 3 DQF) and $\eta_2$ is applied to events in the clean set (not in coincidence with a DQF). These thresholds have been selected in order to ensure a IFAR $\geq \eta$.
