We study the development and saturation of the $m = 1$ one-armed spiral instability in remnants of binary neutron star mergers by means of high-resolution long-term numerical relativity simulations. Our results suggest that this instability is a generic outcome of neutron stars mergers in astrophysically relevant configurations; including both “stiff” and “soft” nuclear equations of state. We find that, once seeded at merger, the $m = 1$ mode saturates within ~ 10 ms and persists over secular timescales. Gravitational waves emitted by the $m = 1$ instability have a peak frequency around 1 – 2 kHz and, if detected, could be used to constrain the equation of state of neutron stars. We construct hybrid waveforms spanning the entire Advanced LIGO band by combining our high-resolution numerical data with state-of-the-art effective-one-body waveforms including tidal effects. We use the complete hybrid waveforms to study the detectability of the one-armed spiral instability for both Advanced LIGO and the Einstein Telescope. We conclude that the one-armed spiral instability is not an efficient gravitational wave emitter. Its observation by current generation detectors is unlikely and will require third-generation interferometers.

I. INTRODUCTION

With the recent detection of gravitational waves (GWs) from a pair of merging black holes (BHs) [1], we have entered the era of GW astronomy. Binary neutron star (BNS) mergers are among the targets for the latest generation of laser-interferometer GW detectors Advanced LIGO [2], Advanced Virgo [3], and KAGRA [4]. The direct detection of GWs from BNS mergers will reveal important aspects of the physics and astrophysics of NSs. Accurate phasing measurements of the GW signal during the late inspiral and merger in combination with robust theoretical predictions, *e.g.*, [5, 6], will provide accurate and nearly model-independent measurements of masses and radii of NSs. This will help constrain the unknown physics of matter at supernuclear densities [7–9].

Recent observations of NSs with masses $\sim 2 M_{\odot}$ [10, 11] in combination with the distribution of NS masses in galactic binaries, which peaks at $\sim 1.35 M_{\odot}$ [12, 13], suggests that the typical outcome of mergers is the formation of a stable remnant or of a hypermassive neutron star (HMNS). The latter is a metastable object that may survive for several tens of milliseconds before collapsing to a BH [14–22]. The merger remnant is an efficient GW emitter [22] and its gravitational radiation has discrete features (peaks) that could be used to provide additional constraints for the high-density part of the NS equation of state (EOS) [18, 20, 23–28]. However, the prospects for detecting this signal are diminished by its high-frequency (2 – 4 kHz), which puts it outside of the maximum-sensitivity band of current GW detectors.

Recently, [29, 30] considered the merger of spinning NSs on eccentric orbits and found that the resulting HMNS develops an $\ell = 2$, $m = 1$, one-armed spiral instability. Because of its $m = 1$ nature, this instability results in GW emission at half the frequency of the dominant $m = 2$ quadrupole mode, in a band of higher sensitivity for GW detectors. Similar instabilities have been previously identified in isolated differentially rotating NSs models [31, 32] and in NSs newly-formed in core collapse, *e.g.*, [33–35]. There are also strong indications of the presence of an $m = 1$ instability in previous simulations of spinning BNSs mergers in quasi-circular orbits [36, 37]. However, the impact of this instability for GW observation of BNS mergers is unclear. Especially in the case of binaries with slowly rotating or nonrotating NSs in quasi-circular orbit, which are presumably the most common.

In this paper we present results of high-resolution numerical relativity (NR) simulations suggesting that the growth of an $m = 1$ instability is a generic outcome of BNS mergers and independent of the NS EOS. The one-armed spiral instability is only weakly damped and persists for several tens of milliseconds. However, we find that the one-armed spiral instability is an inefficient emitter of GWs. Their detection by current and near-future ground-based GW observatories is unlikely.

FIG. 1. Color coded rest-mass density in the orbital plane for our highest-resolution MS1b simulation at representative times after merger (t_0). In the upper panels: merger and development of the $m = 1$ instability. In the bottom panel: roughly half a cycle of the saturated spiral mode. The 180° rotational symmetry of the system is broken by hydrodynamic instabilities originating at the Kelvin-Helmholtz-unstable shear layer between the two stars shortly after merger. This causes the spiral mode to grow. Animations of the density in the orbital plane for both MS1b and SLy binaries are available as supplemental online material and at <https://stellarcollapse.org/BNSm1>.

II. NUMERICAL MODEL

We consider the GW-driven merger of two equal mass $q = M_A/M_B = 1$, $M_A = M_B = 1.35 M_\odot$ NSs. We construct quasi-circular initial data in the conformally flat approximation assuming irrotational flow [38]. We treat NS matter as a perfect fluid and use two nuclear-theory-motivated piecewise polytropic EOS [39] to close the equations of general relativistic (GR) hydrodynamics. The EOS that we employ are designed to fit the SLy [40] and MS1b [41] interaction models. With maximum non-rotating NS masses of $2.06 M_\odot$ and $2.76 M_\odot$ respectively, these two EOS are representative choices of a “soft” and a “stiff” EOS. Thermal effects during the evolution are included using a gamma-law EOS component with $\Gamma_{\text{th}} = 1.75$ [42]. The initial separation between the centers of the two NSs is 50 km, corresponding to approximately 9 and 11 orbits before merger for the MS1b and SLy models, respectively.

The simulations are performed using the `Einstein Toolkit` [43]. For the spacetime evolution we use the `Z4c` formulation [44] of Einstein’s equations, implemented in the `CTGamma` code [45]. The GR hydrodynamics equations are solved using the high-order `WhiskyTHC` code

[46–48]. Our numerical grid covers a cubical region of $2048 M_\odot \simeq 3025$ km centered around the center of mass of the system. We enforce reflection symmetry across the $z = 0$ plane. We use the adaptive mesh refinement driver `Carpenter` [49] to set up a grid consisting of 7 refinement levels, with the finest ones being dynamically moved to follow the centroids of the two NSs. The inner most refinement level contains the NSs during the inspiral and the HMNS after merger. For each EOS we perform simulations with four different resolutions having grid spacing, in the finest level, $h = 0.25 M_\odot, 0.2 M_\odot, 0.15 M_\odot$, and $0.1 M_\odot$ (corresponding to approximately 369 m, 295 m, 222 m, and 148 m). For the time integration, we use a third order strong stability-preserving Runge-Kutta method [50] with the Courant-Friedrichs-Lewy factor set to 0.15 to be able to use the positivity preserving limiter presented in [48]. Finally, for our analysis, we consider up to the $\ell_{\text{max}} = 4$ multipole of the gravitational radiation as extracted at future null-infinity \mathcal{J}^+ using the gauge-invariant Cauchy characteristic extraction method developed by [51].

FIG. 2. GW luminosity of the $\ell = 2$, $m = 2$ and $\ell = 2$, $m = 1$ modes for all simulations as a function of time from merger ($t-t_0$). The data are multiplied by a factor of two to account for the symmetry between positive and negative m . A contribution from the $m = 1$ mode is present in all simulations, especially at high resolution. GWs from the spiral mode are subdominant during most of the evolution, but show negligible damping.

III. ONE-ARMED SPIRAL INSTABILITY

The MS1b merger results in the creation of a stable NS, thanks to the large maximum mass supported by this EOS. The SLy binary forms a short lived HMNS. We find the survival time to be resolution-dependent with the $0.25 M_\odot$, $0.15 M_\odot$, and $0.1 M_\odot$ simulations showing apparent horizon formation at approximately 62.8 ms, 16.3 ms, and 14.9 ms after merger, defined as the time t_0 when the amplitude of the $\ell = 2$, $m = 2$ of the GW strain peaks. We do not continue the SLy $h = 0.2 M_\odot$ simulation until BH formation.

In all our simulations we observe a spontaneous symmetry breaking of the system (*e.g.*, [52]): small asymmetries due to the floating point truncation error in our code are amplified by the turbulence generated by the Kelvin-Helmholtz instability in the contact region between the two stars [16]. This seeds physical odd- m instabilities in the merger remnant. Eventually, the $m = 1$ mode becomes the dominating mode violating the 180° -rotational-symmetry (π -symmetry) of the initial data. The $m = 1$ mode saturates within ~ 10 ms of merger.

Figure 1 shows that for the MS1b binary with $h = 0.1 M_\odot$, the one-armed spiral instability appears to develop similarly to the case of eccentric mergers [29, 30]. Hydrodynamical vortices are formed at the time of merger (under-dense regions in the first panel of Figure 1). These vortices subsequently migrate toward the center where they join. This displaces the forming core of the merger remnant and triggers the development of a spiral arm. Note that some previous studies (*e.g.*, [29, 30, 53, 54]) suggested that toroidal (maximum density in a torus around the center) rather than spheroidal (centrally condensed) stellar structure was necessary for the one-armed to develop. We do not find this to be the case: while our models exhibit slightly off-center density

peaks, they are globally spheroidal (*cf.* also [33–35]).

We estimate the strength of the one-armed spiral instability in an unambiguous way from the multipole decomposition of the GW energy and angular momentum fluxes at \mathcal{J}^+ . These are obtained from the spin -2 weighted spherical harmonics decomposition of the strain $h_{\ell m}$ at future null-infinity following [55]. The multipoles of the energy flux carried by GWs are

$$(L_{\text{GW}})_{\ell m} = (\dot{E}_{\text{GW}})_{\ell m} = \frac{1}{16\pi} |\dot{h}_{\ell m}|^2, \quad (1)$$

while the multipoles of the angular momentum flux are

$$(\dot{J}_{\text{GW}})_{\ell m} = \frac{m}{16\pi} \Im[h_{\ell m} \dot{h}_{\ell m}^*]. \quad (2)$$

We show the $\ell = 2$, $m = 1$ and $\ell = 2$, $m = 2$ quadrupole modes of the GW energy flux in Figure 2. While the $\ell = 2$, $m = 2$ mode peaks at merger and then decays over a timescale of several milliseconds, the $m = 1$ mode grows after merger and saturates within a few milliseconds for both the MS1b and SLy binaries. In both cases, the mode appears to not be damped by hydrodynamical processes and persists for the entire duration of the simulations, *i.e.*, up to 50 ms after merger in the MS1b case, or until BH formation in the SLy case.

The energy released in GWs by the one-armed spiral instability is several orders of magnitude smaller than that from the dominant $\ell = 2$, $m = 2$ mode. The $m = 1$ GW emission is not dynamically relevant for the evolution of the remnant in the first several tens of milliseconds. Even on secular timescales (for the MS1b binary) the $m = 1$ mode does not appear to be efficient at removing angular momentum from the remnant with $J/(2\dot{J}_{\text{GW}})_{\ell=2, m=1} \gtrsim 100$ s. For this reason, the $\ell = 2$, $m = 1$ is only very weakly damped by GW back-reaction. This is in contrast with the behavior of the

dominant quadrupole mode, which is a highly efficient emitter of GWs and, for this reason, it is strongly damped over a timescale of ~ 10 ms [22]. After the $\ell = 2$, $m = 2$ mode has decayed, the $\ell = 2$, $m = 1$ mode becomes the most luminous mode. As shown in Figure 2, this happens already 20 ms after merger in the highest-resolution MS1b simulation. The dominance of this mode over long timescales suggests that the one-armed spiral instability might leave some imprint on the GW signal if it survives for sufficiently long time.

Figure 2 also shows that numerical viscosity in low-resolution simulations can prevent the one-armed spiral instability from fully developing. One could speculate that one of the reasons why this instability has gone undetected for long time is that it might have been suppressed in simulations performed at lower resolutions and/or using more dissipative numerical schemes than those used here. Another reason is the π -symmetry that is assumed in many previous simulations, which obviously prevents the instability completely. Finally, we also remark that, while the instability is very evident for stiff EOS (Figure 1), it is less so in the case of softer EOS (e.g., in our SLy model). In the latter case, it is difficult to identify from the inspection of density colormaps. A modal decomposition of the density distribution or an analysis of the GW multipoles are necessary to unambiguously reveal it.

IV. HYBRID WAVEFORMS

We construct the complete GW signal in the Advanced LIGO band from our binaries by hybridizing our NR waveforms with the tidal effective-one-body (EOB) model presented in [6]. We generate EOB waveforms using a publicly available code [56], starting at a frequency of $\simeq 10$ Hz, corresponding to $\simeq 18$ minutes before merger, and extending up to the moment of merger [6, 57]. We include multipoles up to $\ell = 4$. The resulting hybridized waveforms are available from [58].

We align NR and EOB data as in [6]. We use the difference between the two highest resolutions as a conservative estimate for the numerical uncertainty in the $\ell = 2$, $m = 2$ GW phase predicted by our simulations. The difference is less than 3 radians at merger and less than 0.3 radians in the time window where we perform the alignment with EOB. Excluding the lowest resolution simulation, which appears not converged, we find better than third order convergence in the phase and amplitude of the $\ell = 2$, $m = 2$ GW mode for both the MS1b and the SLy binaries until shortly before merger. This is similar to what was reported in [47]. As a consequence, the de-phasing between the NR and EOB waveforms is dominated by the residual orbital eccentricity and the residuals are essentially flat until shortly before merger as in [6].

In order to be able to estimate the detectability of the one-armed spiral mode, we extend the $\ell = 2$, $m = 1$ GW

signal of the MS1b binary to $\simeq 1$ second after merger using a simple damped sinusoid. This is justified by the fact that the $\ell = 2$, $m = 1$ GW signal from our MS1b simulations has a very stable instantaneous frequency and a narrow spectrum. Since the $\ell = 2$, $m = 1$ GW amplitude in our simulations shows low frequency oscillations of unclear origin, we are not able to reliably estimate damping times from our data. Instead, we heuristically set the damping time of the $\ell = 2$, $m = 1$ mode in our hybrid waveform to 100 ms. This value is consistent with the amplitude evolution of the $h = 0.15 M_\odot$ run, but somewhat smaller than what could be inferred from the $h = 0.1 M_\odot$ data. However, other physical processes, such as neutrino cooling and angular momentum redistribution due to magneto-turbulence, will likely become dominant over such timescales [19] and might damp the one-armed spiral instability [59–61]. As a consequence, our estimate of the survival time of the $m = 1$ mode should constitute a reasonable upper limit.

V. DETECTABILITY

In Figure 3, we show the spectrum of the effective GW signals for the highest resolution MS1b and SLy hybrid waveforms. For our analysis, we assume an optimistic distance of 10 Mpc to the source, an optimal sky location, and an edge-on orientation of the binary with respect to the detector, which is optimal for the detection of the $\ell = 2$, $m = 1$ mode. We also superimpose the sensitivity curves of Advanced LIGO in its zero-detuning high-laser-power configuration [62] and of the proposed ET [63].

We find the spectrum of the GW signal generated by the one-armed spiral instability to reach its maximum at a frequency half of that of the dominant quadrupole peak f_2 . It is thus conceivable that the detection of GWs from the $m = 1$ instability could be used to constrain the NS EOS, since f_2 has been shown to encode properties of the EOS at high densities [18, 23, 25].

We quantify the detectability of the different components of the GW signal by computing optimal signal-to-noise ratios (SNRs), *i.e.*, assuming an optimal detection template [64], for Advanced LIGO and ET using the hybrid waveforms obtained from the highest resolution NR simulations. We compute the SNR integrals using $h_+(f)$ over the frequency windows $9 \text{ Hz} \leq f \leq 8192 \text{ Hz}$ and $1 \text{ Hz} \leq f \leq 8192 \text{ Hz}$ for advanced LIGO and ET respectively. We estimate low-frequency ($f \lesssim 12 \text{ Hz}$) contributions to the SNR by extending the hybrid spectrum as a power-law with index $-7/6$ at low frequencies [65]. The results of this analysis are reported in Table I.

Despite its large spectral peak amplitude, the detection of the $m = 1$ mode with current laser interferometers appear unlikely. Even at the relatively close distance of 10 Mpc, the optimal SNR for the $\ell = 2$, $m = 1$ GW mode of the hybrid MS1b waveform is only $\simeq 1.6$ for advanced LIGO. For comparison, the threshold on the optimal SNR for detection is typically set to 8 [66]. This

FIG. 3. Spectrum of the effective GW signal seen edge-on from a distance of 10 Mpc. We show the spectrum of the hybrid waveforms constructed from the highest resolution data and the noise curves of Advanced LIGO and ET. The $\ell = 2$, $m = 1$ spectrum is mostly concentrated in a narrow maximum located at half of the frequency of the $\ell = 2$, $m = 2$ peak.

TABLE I. Single detector SNRs of different components of the GW signal for the MS1b and SLy binaries at a distance of 10 Mpc, seen edge-on, and computed assuming optimal sky location. We quote the SNR of the entire waveform (all multipoles up to $\ell = 4$), the SNR of the $\ell = 2$, $m = 1$ mode $\text{SNR}_{2,1}$, and the SNR for the $\ell = 2$, $m = 2$ mode computed using only the high-frequency ($f \geq 1$ kHz) component of the GW signal $\text{SNR}_{2,2}^{f \geq 1 \text{ kHz}}$.

Detector	Binary	SNR	$\text{SNR}_{2,1}$	$\text{SNR}_{2,2}^{f \geq 1 \text{ kHz}}$
Adv. LIGO	MS1b-M135-Q1	169.4	1.6	5.4
Adv. LIGO	SLy-M135-Q1	169.5	0.1	6.9
ET	MS1b-M135-Q1	2460.5	14.4	47.4
ET	SLy-M135-Q1	2461.6	1.0	61.3

means that the one-armed spiral instability will be undetectable even for nearby events and the $\ell = 2$, $m = 2$ GW mode appears much more promising for detecting post-merger GWs from BNS mergers. This is even more so for the short lived merger remnant of the SLy binary.

We also remark that our analysis refers to the case of binaries seen edge-on. In the face-on case the SNR for the $\ell = 2$, $m = 2$ mode is twice as large, while the $\ell = 2$, $m = 1$ mode is completely suppressed.

VI. DISCUSSION

In combination with previous studies by others [29, 30, 36, 37] our results for equal-mass, irrotational, BNS mergers from quasi-circular orbits strongly suggest that the one-armed spiral instability is a generic outcome of the merger of two NSs. As we demonstrate in the cases of both soft and stiff EOS, even tiny asymmetries, necessarily of numerical origin for exactly equal mass systems, but expected in any astrophysical configuration, are suffi-

cient to trigger the growth of this instability. Once seeded at the time of merger, the one-armed spiral instability quickly grows into a large-scale $m = 1$ spiral density perturbation, which saturates within a time scale of ~ 10 ms. Our results are supported by the analysis of well defined, gauge invariant, quantities at \mathcal{J}^+ , and by a resolution study.

We find that GWs excited by the $m = 1$ mode carry relatively little energy and angular momentum as compared to those of the dominant $m = 2$ mode. As a consequence, the $m = 1$ mode is very weakly damped and may persist over secular timescales, while the $m = 2$ mode decays over a timescale of ~ 10 milliseconds.

The characteristic frequency of the GW emitted by the one-armed spiral instability encodes important aspects of the NS EOS. Unfortunately, as our analysis shows, the direct observation of GWs from the $m = 1$ mode by the current GW detectors appears unlikely. We find that, even using an optimal SNR detection threshold as low as 5, Advanced LIGO at its design sensitivity will be able to detect optimally oriented sources only out to ~ 3 Mpc. In contrast, we find a horizon distances for the post-merger quadrupole mode of ~ 20 Mpc and ~ 27 Mpc for the MS1b and SLy binaries assuming optimal orientation for the $\ell = 2$, $m = 2$ mode. This is in agreement with the more careful analysis of results of conformally flat simulations by [27]. GWs from the one-armed spiral instability will be a target for third-generation detectors such as ET. For the latter, we find an optimal SNR for the $\ell = 2$, $m = 1$ mode of our highest resolution MS1b hybrid waveform of $\simeq 14.4$ at 10 Mpc using the ET-D sensitivity curve [63]. This would put the horizon for the detection of an optimally oriented source at ~ 29 Mpc.

The most important limitation of our study is the omission of magnetic effects. Very strong magnetic fields have been shown to be able to suppress this instability in isolated NSs [60]. Muhlberger et. al [61], however, found

that large scale hydrodynamical instabilities in isolated differentially rotating NSs are not affected and in some cases are even amplified by the presence of magnetic fields over a large range of magnetic field strengths.

As a side product of the present study, we constructed, for the first time, high-quality hybrid waveforms employing state-of-the-art analytical models and high-resolution high-order NR data. These waveforms are available from [58].

ACKNOWLEDGMENTS

We thank Stefan Hild for the ET-D noise curve data and acknowledge useful discussions with L. Baiotti, W. E. East, F. Galeazzi, W. Kastaun, K. Kiuchi, L. Rezzolla, M. Shibata, and K. Takami.
